ABSTRACT
This paper presents a novel technique for measuring the mechanical forces exerted by a living MultiCellular Tumor Spehroid (MCTS) during growth. We used high aspect ratio microfabricated polydimethylsiloxane (PDMS) pillars as force sensors. During growth, spheroids induce a deformation of the micropillars, which is the parameter we used in order to measure the exerted forces. From 3 dimensional imaging of micropillars induced deflection and mechanical simulation, we were able to measure the force exerted by mammary cancer cell (MCF7) spheroids. Using this methodology we found a value of force of the order of 100-300 nanoNewtons.

KEYWORDS: Micro-tumors, Spheroids, Force, Volumetric imaging, Mechanical simulation.

INTRODUCTION
Tumor cells are known to be sensitive to external mechanical stimuli but little is known about the intrinsic growth-associated mechanical properties of micro-tumors [1]. In that context, the changing forces that a micro-tumor exerts on its microenvironment need to be better characterized. A MCTS is a 3D complex system that reproduces cell-cell and cell-matrix interactions and exhibits a cellular architecture that mimics micro-tumor organization. Many approaches have been developed to study the mechanical properties of spheroids. It includes cellular capsules to measure the pressure exerted by a spheroid [2], parallel plate tensiometry for rheological studies [3] or the micropipette technique to study the response of cellular aggregates to external stresses [4]. Our work differs from those mentioned before, firstly, by its high throughput and the ability to investigate a large number of spheroids within the array of microdevices at the same time. Secondly, our system enables to measure the force directly exerted by the spheroid during growth on its surrounding in the nanoNewton scale and for a large period of time without a drastic perturbation of the cell organization within the spheroid under investigation.

EXPERIMENTAL
The produced devices are arrays of high aspect ratio (1:10), round and flexible PDMS pillars, of 300 μm in height, identical in diameter and circularly distributed around a space where the spheroid will be placed. Each pillar is used as a force sensor by a simple recording of its bending. We fabricated devices of different pillar diameters in order to study the effect of the stiffness on the intensity of the generated forces. The technological challenge behind these devices was the optimization of a process capable to produce PDMS beams high enough compared to the MCTs (around 300 μm), soft enough (stiffness around 10 nN/μm) for measuring nano-newton scale forces, while preventing their mechanical collapse [5]. In order to measure forces exerted by growing spheroids, the deformations of the pillars and the contact zone of the spheroid with the microdevice are required. The growth of cancer cells spheroids was recorded by taking 3D confocal images for fluorescently stained microdevices and cells expressing a fluorescent marker (Figure 1).
RESULTS AND DISCUSSION

Spheroid growth induced bending of the micropillars, reflecting the forces exerted by the spheroid. On one hand, in order to characterize the 3 dimensional deformations of the pillars from the 3D confocal images, we developed a homemade MATLAB program that enables the quantification of a large number of devices at one time point (Figure 2).

On the other hand, we used finite element method through the software COMSOL, to simulate the bending of the PDMS pillars. From various images, we were able to localize the contact region where the spheroid exerts its efforts on the pillars. Then by simulation, we could calculate the displacement field and the stress accumulated in the pillars for a large range of applied forces. The simulation results were then compared to the 3D experimental displacement in order to extract the value of the force responsible for this deformation (Figure 3).
Using this procedure of force calculation, we recorded the forces exerted by MCF7 spheroids on the microdevices after a period of 4 days of contact between the spheroids and the microdevices. Our results showed that the forces exerted on a device with micropillars of 28 µm in diameter are in the order of 100-300 nN. Moreover we have found that spheroids confronted with stiffer pillars (36 µm in diameter), exerted slightly higher forces as shown in Figure 4.

**CONCLUSION**

In this study, we offered a new methodology to investigate systematically the mechanical properties of spheroids with a high throughput. We gave for the first time a range of forces exerted by a living MCTS on its surroundings. In previous work we have shown the dynamic interaction between the spheroids and the microdevice [5], which opens a new perspective towards kinetics studies of the evolution of forces within a growing spheroid, in time. This method also opens original perspectives for pharmacological drug screening and for investigating the mechanisms of growth of micro-tumors.
